20. ABSTRACT (Continue on reverse side if necessary and identify by block number)

This thesis describes the detailed interface design and implementation of the Micropolis 1220 rigid disk storage unit into the AEGIS multiuser environment. At the onset of this work, the AEGIS development system consisted of an MBB-80 bubble memory, the REMEX Data Warehouse disk system, and four INTEL iSBC 86/12A single board computers. The Micropolis

(continuation of absrtact)

interface was accomplished utilizing the INTEL 8255 programmable parallel I/O port resident on one of the AEGIS iSBC 86/12A computers. The iSBC 86/12A used for the interface can still be operated as an independent computer with all Micropolis disk operations being transparent to the user. The Micropolis disk unit adds an additional 35.6 megabytes of online storage to the AEGIS system. Utilization of the Micropolis disk system as a software development storage media will free the REMEX Data Warehouse for storage of "radar data" to emulate the SPY-1A radar.

B. GENERAL DISCUSSION

The AEGIS weapons system simulation project is an ongoing study currently being conducted at the Naval

Postgraduate School. The primary objective of this study is to investigate the feasibility of replacing the present. four-processor AN/UYK-7 mainframe computer with a multiple microcomputer based architecture.

The primary mission of the multiprocessor system is to provide computer control for the SPY-1A radar system. This system collects large amounts of data concerning target detection and acquisition which must be processed in real-time. A microcomputer based system can provide the same signal processing in real-time only if more than one processor is used and the computations are performed concurrently.

Thus, the first logical step of the AZGIS study was to identify a viable microcomputer and design an efficient operating system capable of managing concurrent processes. A detailed design of such an operating system was presented by Wasson in 1980 [Ref. 1]. This design was based on the INTEL iSBC 85/12A microcomputer. This is a single board computer based on the INTEL 8086 16-bit microprocessor. The operating system. MCORTEX, was implemented using Wasson's design and refined many times. Klinefelter demonstrated the first truly efficient implementation of MCORTEX with four iSBC 85/12A's in June of 1982 [Ref. 2].

Because MCORTEX was a very specialized manager of concurrent processes, it was not an operating system well suited for program module development. Thus, the next

logical step of the project was to identify an operating system that could be easily integrated into the same nardware utilized by MCORTEX. This would allow the same system to be used for both signal processing emulation by MCORTEX and as a software development tool. CP/M-86, developed by Digital Research for use with the INTEL 8086 microprocessor, was chosen for this purpose. This choice offered the maximum in flexibility in that this operating system could be user configured for different or changing nardware environments.

Mike Candalor began the integration process by modifying the Basic Input/Output System (BIOS) or CP/M-86 for use on an INTEL MDS system. This was demonstrated in June of 1981. [Ref. 3]

Hicklin and Neufeld continued the integration process by adding a bubble memory to the MULTIBUS and again altering the BIOS to reflect the current nardware [Ref. 4]. Due to the non-volatile nature of a bubble memory, it was used in this application to store the CP/M-86 operating system. This permitted a fast, easy method of downloading the operating system into random access memory (RAM) when power was applied to the system.

Since the Klinefelter demonstration employed simulated processes, it was necessary to develop a method by which the SPY-1A radar could be emulated in real-time. A hard disk

drive, interfaced through direct memory access (DMA), was determined suitable for this purpose due to its high speed and large storage capacity. It was also considered desirable to make maximum use of the available hardware when the system was being operated in the software development mode. This required that each single board computer have the capability of supporting an independent user. These two concepts were brought together and demonstrated with a four-board, multi-user system by Almquist and Stevens in December 1982. [Ref. 5]

At this point the system still lacked a capability of storing software for future refinement. This thesis completes the program development system by presenting the nardware interface design and software implementation of the Micropolis disk drive into the multi-user system as developed by Almquist and Stevens.

C. FORMAT OF THESIS

Chapter I gives a general overview of the AEGIS research effort. It also provides a general developmental history of the project and explains why the research work accomplished by this thesis was essential to the project.

Chapter II addresses the system architecture. Detailed discussion is given or all major nardware components as this was the existing hardware environment into which the Micropolis disk drive had to be interfaced.

Chapter III describes the details of the AEGIS multiuser system software. The standard CP/M-86 operating system is discussed in moderate detail. Also covered in this chapter is a powerful medification to CP/M-86 that was developed during prior work. This modification provides a simple and efficient method for altering the nardware environment supported by the operating system.

The hardware interface developed for the Micropolis fisk system is presented in Chapter IV. First, the details of the requirements imposed on the design of the interface by the Micropolis controller are presented. This is followed by the development of a functional interface to meet those requirements.

Chapter V presents the software implementation of the Micropolis into the CP/M-86 operating system and Chapter VI summarizes the development work accomplished during this thesis. Included in Chapter VI is a comparison of the disk access times required by the REMEX Data Warehouse (a DMA interfaced hard disk) and the Micropolis disk system (a programmed I/O interfaced hard disk).

II. SYSTEM ARCHITECTURE

As stated in the introduction, the design of the MCORTEX operating system and the software development system was based on the INTEL iSBC 86/12A single board computer and various peripheral components. Figure 2.1 depicts the interconnection of these components as they existed at the onset of this research effort. In the paragraphs that follow, a description of each component, as well as its role in the overall system, is given. An exhaustive description of each device can be found in the cited references.

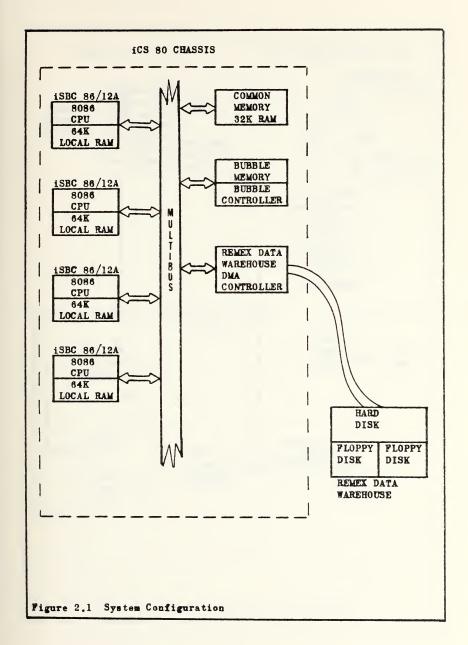

A. INTEL 8086

The INTEL 8086 is a night performance, general purpose 16-bit microprocessor. It is the foundation upon which the AEGIS developmental system is built. Refer to Figure 2.2 for a general overview of its internal structure and organization. This section is intended to give general knowledge about this device. A detailed description can found in [Ref. 6].

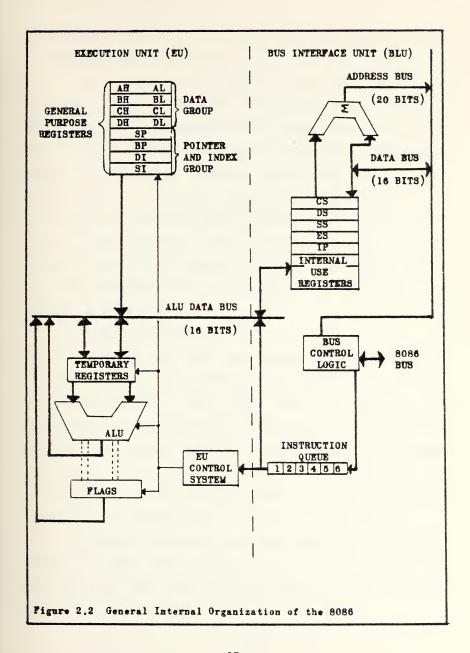

1. <u>General Purpose and Flags Registers</u>

As can be seen in Figure 2.2, there are eight 16-bit general purpose registers. Four of these are byte or word addressable and are referred to as "the data group". The

remaining four are only word addressable and are referred as "the pointer and index group".

The flags register is 16 bits wide and consists of nine usable status bits. The remaining seven are underined. The nine bits are divided into six status flags and three control flags. The status flags are set by the 8086 as the result of arithmetic or logical operations. The control flags are set through programmed instructions. Or particular importance is the IF control flag. This flag is used to enable/disable maskable interrupts and must be properly set for the system to function correctly. The IF or interrupt—enable flag is discussed in greater detail in Section 4 of this chapter.

2. Segment Registers

Although the 8086 has segment registers and the technical literature discusses segmentation as related to the microprocessor, this should not be confused with segmentation as is generally defined for operating systems. The operating system definition supports the ideas of memory management and segment access checks but the 8086 has no special hardware that supplies these functions. However, addressing is segment-like in that it is two-dimensional.

Physical addresses are generated from two 16-bit values: a base and an offset value. The base value is shifted left four bits and the offset is added to this

snifted version to arrive at a physical address. As an example, consider the following:

E000 -- BASE VALUE ZAAA -- OFFSET VALUE

When these two hexidecimal values are added as described above, the result is:

E2000 -- SHIFTED BASE VALUE

2AAA -- OFFSET VALUE

EZAAA -- PHYSICAL ADDRESS

It is the segment registers that supply the base value. This method of addressing results in a 20-bit address or a one megabyte address space.

in Figure 2.2 are four segment registers. Each are 16 bits wide and give the 8086 access to kilobytes oβ memory. Assuming they are each set to 64K base, this will give the CPU access different t o maximum of 256K bytes of memory at any instant of time. Because the segment registers are accessible to the software, they can be programmatically altered to any value. Thus allowing addressing throughout the entire one megabyte range.

Which segment register is used and now the offset value is obtained depends upon the instruction currently being executed. The CS or code segment register points to the current code segment. All executable instructions are

located in this segment. Therefore, the address of the next instruction is computed using the CS register as the base and the instruction pointer (IP) as the offset. All stack operations utilize the stack segment (SS) register as the base and the stack pointer (SP) as the offset. The data segment (DS) register and the extra segment (ES) register have no explicit offset register associated with them. This value is software controlled by supplying one of the registers in the pointer and index group as a part of the instruction. Program variables are generally placed in the memory space accessible by these two segment registers.

3. Execution and Bus Interface Units

The dividing line in Figure 2.2 is used to indicate two separate processing units within the 8086: the execution unit (EU) and bus interface unit (BIU). Both of these units operate independently.

The BIU is responsible for performing all bus operations for the BU. It generates 20 bit addresses by combining the segment and offset values in its own adder and transfers data to and from the EU on the ALU data bus. The BIU also fetches instructions for the EU and stores them in its six byte instruction queue. This queue makes it possible for the BIU to "prefetch" instructions during any spare bus cycles.

The EU is responsible for executing all instructions and for transfering data and addresses to the BIU. It also

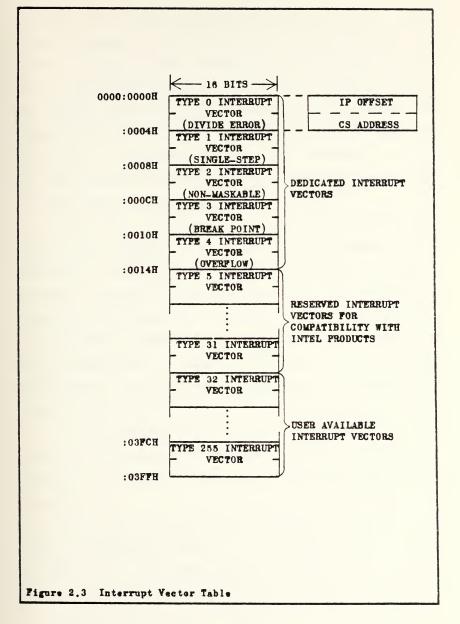

maintains the general purpose and flags registers. Because there is no connection from the EU to the system bus, it is isolated from the outside world. All instructions to be executed are fetched from the BIU's instruction queue. In the event that the queue is empty, the EU simply waits for the BIU to place an instruction in the queue.

This type of architecture allows extensive overlapping of instruction fetch with execution. The result is that the time required to fetch instructions becomes nearly transparent to the EU since it works on instructions that have been prefetched. This, coupled with a 5 MHZ clock, gives the 8086 the high speed necessary for the AEGIS implementation.

4. Interrupt Structure

The 8086 has provisions for up to 256 different interrupts numbered from 0 to 255. When an interrupt occurs, the CPU must transfer control to a new program location that contains the necessary programmed instructions to service that interrupt. Two values are necessary to effect the transfer: the code segment in which the interrupt routine is located and the instruction pointer for the routine. These values are located in a table that begins at absolute zero in memory and extends to 3FF hexidecimal. Refer to Figure 2.3. The information needed for each interrupt routine occupies four consecutive bytes in this table. The CPU is

supplied with a type code when an interrupt occurs. This value is automatically multiplied by four to determine the correct position in the table from which to obtain the CS and IP values. The current CS, IP and flags register values are pushed on the stack and the new CS and IP values are loaded. This completes the transfer of control. Both the values in the interrupt table and the interrupt routines are user supplied and must be placed in memory before the interrupt can be permitted to occur.

How the processor is supplied with the type code cited above depends on the method used to generate the interrupt. These can be software or hardware generated. Eardware interrupts are subdivided into two categories: maskable and non-maskable. Maskable interrupts are enabled or disabled by setting or clearing the IF flag. When the CPU acknowledges a maskable interrupt, it is the responsibility of the hardware requesting the interrupt to place the type code on the bus for use by the CPU.

Non-maskable interrupts cannot be disabled. In the event of a non-maskable interrupt, the CPU automatically assigns it a type code of 2. Thus, a type code need not be supplied.

Software interrupts can be invoked by executing the "INT n" instruction; where "n" is a number from 0 to 255. In this case, the type code is an explicit part of the instruction. They can also occur by creating a fatal error

as a result of program execution, such as a divide ty zero or overflow error. The CPU will then use a predefined type code as depicted in Figure 2.3.

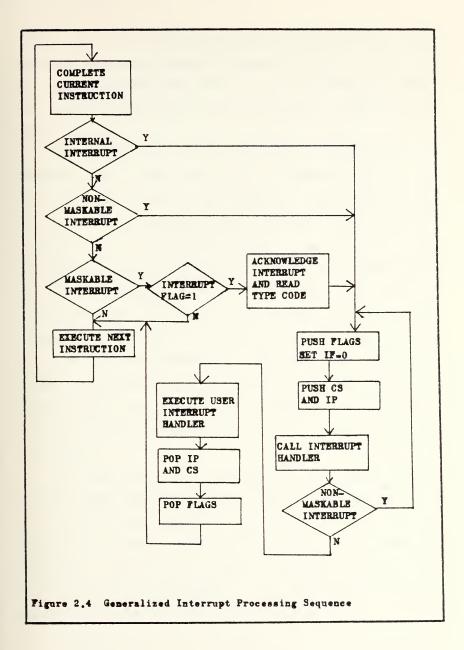

The 8086 does not generally control the devices that can cause interrupts. This makes simultaneously occurring interrupts possible and therefore, all interrupts are prioritized. Shown in Figure 2.4 is the interrupt processing sequence used. This figure indicates that software generated interrupts are the highest priority. Non-maskable are the next nightst and maskable are the lowest.

The interrupt structure discussed above plays an important role in the development of the Micropolis interface design. A general understanding of this structure is an essential prerequiste to an understanding of both the detailed design presented in Chapter IV and the software implementation presented in Chapter V.

B. THE iSBC 86/12A

The iSBC 86/12A is a complete single board computer. It is used as the central processing node of the AEGIS multiprocessor system. The board includes the 8086 16-bit CPU, 64K bytes of RAM, a serial communications interface, an INTEL 8255 that supplies three programmable parallel I/O ports, an INTEL 8253 programmable timer, an INTEL 8259A priority interrupt controller, MULTIBUS interface control

logic, and bus expansion drivers for interface with other MULTIBUS interface-compatible expansion boards. Provisions are also made for installation of up to 16K bytes of EPROM. The current system only utilizes 8K bytes of EPROM on each board.

onboard 64K bytes of RAM can be dual-ported in segments of 16K bytes thus making it accessible not only to the local CPU but also to the MULTIBUS. When dual-ported, the RAM can be switch-and-jumper configured to any 128K byte segment of the one megabyte address space relative to the MULTIBUS. Local addresses are always fixed tetween 2000H and FFFFH regardless of the MULTIBUS address the board configured for. This system was designed for independent operation by each SBC and therefore, no RAM is dual-ported. make the RAM inaccessible to the MULTIBUS requires a jumper between E112-E114 on each SBC. The board does not come factory equipped with this jumper and its existance must be verified before proper operation of the system can be insured.

Each iSBC comes factory configured with jumpers between E103-E104 and E105-E106. These jumpers route the bus clock and constant clock signals to the MULTIBUS. As shown in Figure 2.1, several SBC's are connected to the MULTIBUS interface. Only one of these is required to supply the clock signals to the MULTIBUS. All other boards must have the E103-E104 and E105-E106 jumpers removed.

No other special configurations are necessary for the iSBC 86/12A boards. For a complete discussion of user options and factory defaults for this board see [Ref. 7].

C. MBB-80 BUBBLE MEMORY

The MBB-80 Bubbl-Board is a memory storage device that is compatible with all 8-bit and 16-bit microprocessors having INTEL MULTIBUS architecture. The board provides approximately 90% bytes of non-volatile memory as well as all required MULTIBUS interface logic.

Interface with the MBB-80 controller is accomplished through memory mapped I/O and requires sixteen user-defined locations in the MULTIBUS one megabyte address space. These addresses correspond to controller registers that are used to read status, set board configurations and perform read/write operations. The current configuration uses MULTIBUS addresses beginning at 80000H. This requires that switch 8 in S2 on the Bubbl-Board be set to "on" and all others in S2 be set to "off". All switches in S1 must be set to "off".

The bubble memory appears to the system as a simple 90k byte disk drive. All read/write operations to this device are accomplished in the same manner used for any other disk system and require no special user invoked functions. Its primary use in the system as depicted in Figure 2.1 is as a non-volatile storage medium from which to load the operating

system into RAM. For a complete discussion of the MBB-80 Bubbl-Board implementation to the system see [Ref. 4].

D. REMEX DATA WAREHOUSE

1. Subcomponents and Storage Capacity

The REMEX Data Warehouse is a mass storage unit containing two floppy disk drives (single or double-sided, single or double density) and a Winchester technology fixed disk drive. Additionally, an MC6800 microprocessor coupled with onboard firmware is the mechanism used to service all drives.

The fixed disk is a 14 inch enclosed disk system consisting of two recording surfaces. Each surface has two recording heads. Each head can access 21% usable tracks and each track contains 39 512-byte sectors. This gives each head access to approximately 4 megabytes of storage and gives the disk a total storage capacity of 16 megabytes.

The two floppy drives are switch-selectable to nandle either single or double density. In this implementation, single density, standard IPM FM encoding is employed.

2. <u>MULTIBUS Interface</u>

The REMEX Data Warehouse is interfaced to the MULTIBUS via the MULTIBUS Interface Card assembly supplied with the unit. This assembly contains all the necessary control, buffering and MULTIBUS interface logic required to

interface with the nost system. The nost communicates with the assembly using programmed I/O. Communications from the assembly to the nost is via DMA. The interface acts as a bus master in the DMA mode and as a bus slave in the programmed I/O mode.

The controller requires 4 I/O port addresses for the nost system communications. These are used to obtain status and pass command information. Currently, addresses 70, 71, 72 and 73 hexidecimal are used but these can be altered by changing the appropriate switches on the MULTIBUS Interface Card assembly.

The system configuration in this implementation utilizes the REMEX Data Warehouse as a program storage media. However, as alluded to in the introduction, it is envisioned that this hard disk drive will be used for storage of track data in the SPY-1A radar emulation effort. For further information on the REMEX consult [Ref. 8].

E. iCS-80 CHASSIS

The iCS-80 industrial chassis is MULTIBUS-compatible and supports a modular microcomputer development system. It consists of four four-slot iSBC 504/614 Caracages, four fans, a power supply and control panel. The control panel contains an on/off/lock key switch, reset and interrupt pushbuttons and various LED's.

Any combination of MULTIBUS-compatible plug in boards can be installed. A maximum of four boards can be placed in the iSBC 504 Cardcage. Additional iSBC 614 Cardcages can be added to the chassis through an expansion interface supplied with the system. The laboratory system utilized in support of this thesis consists of a single iSBC 604 Cardcage and three iSBC 614 Cardcages. This gives a total capacity of 16 board slots. These cages provide for both INTEL MULTIBUS master and slave boards. From the front panel, the slots are numbered 1 to 16 from left to right. All odd-numbered slots are configured for master boards and all even-numbered slots are configured for slave boards.

Because more than one bus master can be placed in the chassis, a priority resolution scheme is required to resolve MULTIBUS access contention. This scheme can be operated in either the serial or parallel mode. In the system of Figure 2.1, the chassis is operated in the parallel mode with an external random priority network for bus access resolution. For more information see [Ref. 9].

F. COMMON MEMORY

The common memory depicted in Figure 2.1 is a simple 32K byte, MULTIBUS-compatible RAM board. It can be switch configured to any address in the one megabyte Multibus address space. In its current configuration, it occupies

addresses E0000H through E7FFFH. The board is expandable to 64K bytes of RAM.

Recall from the discussion on the iSBC 86/12A that the RAM of all SBC's in the system is jumper configured to be accessible only to the local CPU. This means that neither the bubble controller nor the REMEX controller can communicate directly with any iSBC. Therefore, all read/write operations with these two devices is accomplished via the common memory. The technique used to coordinate this effort is a software one and is discussed in detail in the next chapter.

G. MICROPOLIS DISK DRIVE

The Micropolis disk system (not depicted in Figure 2.1) is an eight inch fixed disk drive with an integral controller board. It consists of five data surfaces with 580 tracks per surface. Each track contains twenty-four 512 byte sectors. This gives a 35.6 megabyte formatted storage capacity.

The controller board consists of a Z-80 microprocessor, firmware in PROM, and the necessary control logic and buffers to provide a variety of features. The features employed and the details of the Micropolis interface accomplished as a result of this thesis work are presented in Chapters IV and V.

III. SYSTEM SOFTWARE

The Micropolis interfacing work consisted of two phases: the nardware interface design and the software interface. Before either could be accomplished, it was necessary to understand both the existing system architecture and software. The last chapter addressed that architecture. Therefore, this chapter presents the details of the AEGIS developmental system software.

A. CP/M-86 OPERATING SYSTEM

1. General Discussion

CP/M-86 is the operating system used in the AEGIS software development system. It is a commercially distributed operating system developed by Digital Research for use with a single INTEL 8086 based microcomputer. It is supplied on two single sided, single density, eight inch floppy disks. Included on these diskettes is the operating system (CPM.SYS), an 8086 assembler (ASM86.CMD), the Pynamic Machine Language Debugger (DDT86.CMD), an editor (ED.CMD) and various reconfiguration and file handling utilities.

The CP/M-86 operating system can be user configured to fit any hardware environment. As it is snipped, the file CPM.SYS is configured for 32K bytes of RAM, a keyboard, a screen device, an INTEL iSBC 204 Floppy Disk Controller and

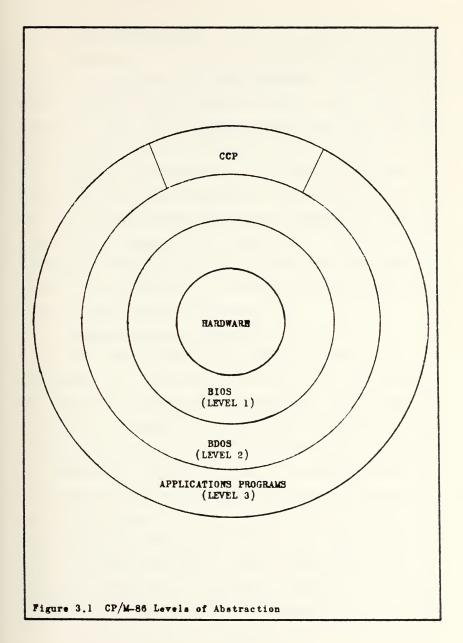

a 9600 band serially interfaced printer. The details of the CP/M structure and the reconfiguration procedures are discussed below. For information on the entire CP/M-86 environment and capabilities see [Ref. 10-12].

2. Structure

The CP/M operating system can be viewed as occupying three distinct levels or abstraction. Refer to Figure 3.1. Applications programs invoke system functions through the Basic Disk Operating System (BDOS) module and do not communicate with any other module. The FDOS performs services requested by applications programs and all general file and disk management functions. All nardware dependent functions required by the BDOS are requested through the Basic Input/Output System (BIOS) module. The BIOS module is the only one that communicates with the nardware. The Console Command Processor (CCP) shown is used to process console commands and provides the user interface in the absence of an applications program.

Since all nardware dependent functions are located in the BIOS module, the system hardware configuration must be reflected here. A skeletal BIOS (BIOS.A86) is provided in source code format for this purpose. The CCP and BDOS modules are provided as a single hex file (CPM.H86). This file requires no modification but is necessary for the adaption/reconfiguration process described in Section 4 below.

3. Bootstrapping CP/M

Loading CP/M into RAM from a standard single density floppy disk requires a two step procedure. The boot ROM, which receives control when the system reset outton is depressed, must load a loader program from the reserved system tracks on the disk into RAM and pass control to it. The loader is then responsible for loading the operating system from the disk into RAM and passing control to it. This two step procedure is required because the operating system is too large to fit on the reserved system tracks. Therefore, adaption of CP/M to a system other than that for which it is commercially distributed requires modification to these three software components.

4. General Adaption Procedures

The major effort in the adaption process is in the development of the hardware drivers for the BIOS module. The BIOS can be classified as performing three types of functions: nardware initialization/reinitialization, character I/O and disk I/O. The functions are contained in 21 subroutines within the module. The BIOS accesses the subroutines through a table that has individual jump vectors to the entry point of each subroutine. This is shown in the operating system memory map in Figure 3.2. The actions that must take place upon entry to each of these subroutines is detailed in [Ref 10: pp. 60-65]. A change in the hardware environment is accounted for by changing the code within

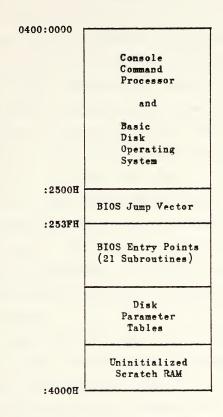

Figure 3.2 Operating System Memory Map

the 21 subroutines and meeting the entry and exit conditions as specified in this reference. Recall that a skeletal BIOS.A86 file is provided as a model for this purpose.

The Disk Parameter Tables snown in the previous figure are used by the BIOS to obtain the characterisatics of each device. These tables exist in a file separate from the BIOS and are included durin assembly through the use of the INCLUDE (filename). (filetype) instruction at the base of the BIOS. The source code for the tables as well as the Uninitialized Scratch Ram Area, can be automatically generated by the GENDEF.CMD utility. This requires a (filename).DEF file as input and produces a (filename).LIB file as output. The contents of (filename).DEF are simple, one line disk definition statements. The format for the statements and their meaning is described in detail in [Rer 10: pp.72-20].

Once the BIOS file is modified and the Disk Parameter Table file created, they are assembled using ASM86.CMD. The resulting nex file is concatenated with CPM.H86 using PIP.CMD and a command file for this single nex file is generated using GENCMD.CMD. Finally, the new operating system that results is placed on the disk as CPM.SYS using PIP.CMD. The process described above is depicted in Figure 3.3. Note that the 8080 model option of CP/M-86 is shown in this example.

- USER.DEF ==> GENDEF.CMD ==> USER.LIB
- 2. USERBIOS.A86 ==> ASM86.CMD ==> USERBIOS.H86
- 3. CPM.H86 + USERBIOS.H86 ==> PIP.CMD ==> CPMSYS.H86
- 4. CPMSYS.H86 ==> GENCMD.CMD ==> CPMSYS.CMD (E080 code[a40])
- 5. CPMSYS.CMD ==> PIP.CMD ==> CPM.SYS (RENAME ON NEW DISK)

Figure 3.3 Steps for Creating a New CPM.SYS

Two software components remain to be adapted: the loader program and the boot ROM program. The loader program is a simplified version of CP/M-86 and contains only enough file processing capability to read the CPM.SYS file from disk to memory. Three files are provided for the development of a loader: LDCPM.H86, LDBDOS.H86 and a skeletal LDBIOS.A86 source file. The LDBIOS.A86 file reflects the hardware to be used in the loading operation and does not necessarily reflect the total hardware. This file contains the same 21 entry points as the BIOS.A86 file with the same entry and exit conditions and requires the same type of Disk Parameter Tables and scratch pad area. The generation of the LOADER. CMD file is depicted in Figure The resulting loader must be small enough to fit 3.4. entirely on the reserved system tracks.

- 1. URLDBIOS.A86 ==> ASM86.CMD ==> URIDBIOS.H86
- 2. LDCPM.H86 + LDEDOS.H86 + URLDEIOS.H86==>PIP.CMD ==> LOADER.H86
- 3. LOADER. H86 ==> GENCMD. CMD ==> LOADER. CMD
- 4. LOADER.CMD ==> LDCOPY.CMD ==> LOADER.CMD (LOAD ON SYSTEM TRACKS)

Figure 3.4 Steps for Creating LOADER.CMD

The development of a boot ROM program depends only on the physical device used to load the operating system. Its single purpose is to load the program located on the system tracks into RAM and pass control to it. A ROM.A86 file is provided that details the boot ROM for an INTEL iSBC 204 Floppy Disk Controller and serves as an excellent example. However, because the method used will vary widely from device to device, no files are provided that simplify this development.

B. AEGIS IMPLEMENTATION OF CP/M-86

1. Boot ROM and Loader

In the AEGIS implementation of CP/M-86 used during the initial development work of this thesis, two boot ROM programs and their associated loader programs were available. Both are located at the base of the INTEL 957 monitor in the 8K byte EPROM of the iSBC 86/12A. The first

allows the system to be booted from either the single or double density INTEL MDS floppy disk drive by executing the command "GFFD4:0" from the monitor. The second will boot the system from the bubble memory by executing "GFFD4:4" from the monitor.

2. A Modification to the BIOS

Recall from Section A-4 above that any hardware change within the system requires some of the 21 BIOS subroutines to be rewritten. A change occurs not only by the addition of hardware but also when a component is removed either because it has failed and there is no replacement or it is no longer needed. In a hardware environment as flexible as that required by the AEGIS project, the standard reconfiguration process becomes an extremely time-consuming task.

To alleviate this problem, a method was developed as a part of Almquist and Stevens' work in which only minor changes to the BIOS were required to alter the hardware configuration. With this technique, all of the FIOS devicedependent subroutines are extracted into a separate file for each unique device. The specific device-dependent routines are: INIT, SELDSK, HOME, SETTRK, SETSEC, READ and WRITE. The physical location of the entry points to the routines is obtained from an ordered label table file and the BIOS accesses the routines through an indexed CALL instruction.

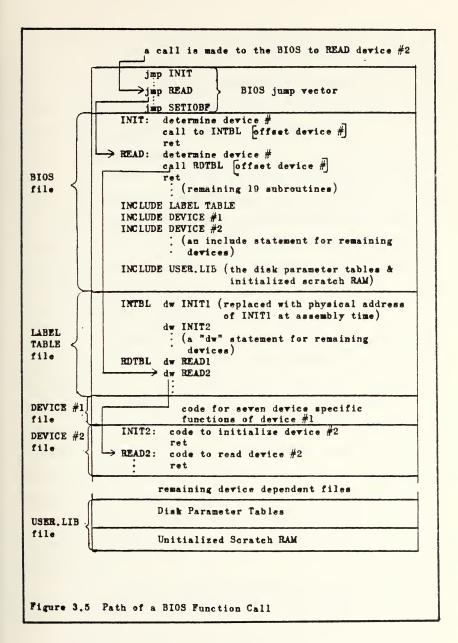

How this technique works is shown in Figure 3.5. In this example, a call is made to the BIOS to READ DEVICE #2. The BIOS makes a jump to the READ entry point. However, instead of doing an actual READ at this point, the device number is determined and a call to the address found in the second position of RDTBL is made. The code that performs the READ function for DEVICE #2 is then executed.

The code for the seven device-dependent functions can be written and debugged independently of any other code. To add the device to the system requires one INCLUDE (filename).(filetype) statement be added to the EIOS file, the corresponding seven entry points be added to the label table file and the Disk Parameter Table be updated. The steps for creating the CPM.SYS file remain unchanged from those presented in Section A-4. To remove a device, the process is reversed. Clearly this method allows the hardware dependent code (and hence, the hareware itself) to be more easily integrated in or removed from the operating system than the standard BIOS structure did.

C. MULTIUSER SYSTEM

CP/M is not a multiuser or multitasking operating system. Another major development of the Aimquist and Stevens' research work was a method by which each single board computer in the system could operate independently of the others under CP/M and still have access to the shared

resources (the disk drives and the bubble memory) of the system. The multiuser system that resulted can be broken down into three functional categories: synchronization of common memory usage, boot loading all SBC's and write protection of a user's allocated disk space.

1. Synchronization

As stated in Chapter II, the RAM on each iSEC 86/12A is not accessible via the MULTIBUS and therefore, all disk and bubble memory read/write operations must be performed through a buffer in the common memory. This requires a synchronization scheme that will ensure a single computer can successfully complete a read/write operation before another computer is permitted access.

A ticket/server technique had been developed for this purpose. This required a CALL REQUEST instruction to be placed prior to all common memory read/write operations and a CALL RELEASE instruction be placed after the read/write operation. The CALL REQUEST accesses the "ticket" variable in common memory for a ticket number and waits until that number is equal to the "server" variable, a number also found in common memory. The read/write operation is then performed and the CALL RELEASE advances the server number, thus releasing common memory to the next ticket holder.

The code for these subroutines is contained in the file SYNC.A86. It is included in the BIOS through an

INCLUDE statement placed immediately following the last INCLUDE statement for the device files.

2. Boot Loading All iSBC's

Because the common memory variables must be initialized only once, two versions of the CP/M-86 operating system had been developed. The file CPMMAST.CMD is the master version that performs the common memory initialization while CPMSLAVE.CMD is the slave version that does not.

The master board is boot loaded with CPMMAST.CMD from the bubble memory. Once this board is operational, the command "LDBOOT" is executed and results in a copy of BOOT.CMD being placed in the common memory. Next, the command "LDCPM" is executed. This places a copy of CPMSLAVE.CMD into common memory. From the monitor of the remaining SBC's, the command "GE0000:0400" is executed. This causes the CPU to execute the code of BOOT.CMD which, in turn, moves a copy of CPMSLAVE.CMD into local RAM and transfers control to it.

3. Disk Write Protection

Disk write protection was achieved through a log-in procedure. A log table is initialized in common memory as a part of the master version initialization. The number of entries in the table correspond to the number of disk drives or logical devices in the system. As part of booting the

operating system, the user is queried for the console number being used (located on the front panel of each console) and the disk drive to log on to. The log table is checked after this entry to determine if the desired drive is free. If it is, the user console number is placed at that drive's position in the log table. If it is not, the user is asked to re-select a drive.

The user console number is also stored in the local variable USER. Write protection is accomplished by comparing the value in USER to the currently selected logical disk number and aborting any write operation if they are not the same.

It was considered desirable to be able to change disk drives without the need to reboot the board. A log out procedure was written for this purpose. When the command "LOGOUT" is executed, the USER variable is reset, the log table is updated and the user is again requested to enter a disk drive to log on to.

The final common memory utilization employed as a result of the multiuser system developed by Almquist and Stevens is depicted in Figure 3.6.

D. MCORTEX

MCORTEX is the operating system that was developed for the SPY-1A radar emulation. In the final version presented by Klinefelter [Ref. 2], MCORTEX was set up to manale ten

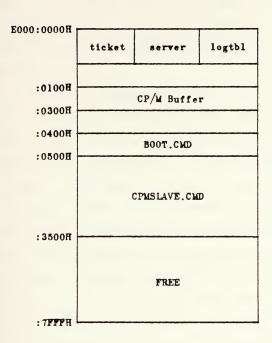

Figure 3.6 Common Memory Allocation Map

virtual processors for each real processor. The data base upon which all scheduling decisions are based is the Virtual Processor Map (VPM) located in common memory. The VPM contains the control and status information on each virtual processor required by MCORTEX to coordinate the consurrent processing.

All processes managed by MCORTEX can be in one of three states: running on a real processor, waiting for some event to occur or ready to run (waiting to gain access to the real processor). If a process is in the waiting state, it could be waiting for an event to occur on a real processor other than the one to which it was assigned. An eventcount table is maintained in common memory for notification purposes. Whenever a real processor completes an event, the table is updated and a message is broadcast to all other real processors in the system that some event has just been completed. Each real processor then checks the eventcount table to determine if the event pertains to any or its virtual processors and reacts accordingly.

The technique used for broadcasting an event employed a type of global interrupt issued on the MUITIBOS. Because the development of the Micropolis interface altered the technique somewhat, the details of it will be presented in the next chapter.

IV. MICROPOLIS HARDWARE INTERFACE DEVELOPMENT

A. OVERVIEW

The Micropolis disk system offers an interface structure that is suitable for use with either programmed I/O or DMA data transfers. In an effort to make maximum use of available system nardware, the programmed I/O mode was used in this implementation. This enabled an interface to be designed with the INTEL 8255 programmable parallel I/O chip located on the iSBC 86/12A.

Recall from Chapter II that all RAM on each SBC is accessible through the MULTIBUS. Therefore, all control, status, and data information intended for the Micropolis disk system had to be passed through the common memory. Because the disk system was interfaced into a single SBC's 8255 port, the disk controller had no method communicating directly with the common memory. To overcome problem, a timer-controlled interrupt was designed. This allowed the 8086 CPU to be interrupted at periodic intervals and effect any necessary communications between common memory and the controller. The distinct advantage of this technique is that the single board computer used for the interfacing can still be used as an independently operating computer with all disk operations transparent to the user.

In the following paragraphs, the details of the interface design and the timer-controlled interrupt design are presented. This discussion is limited to the development of the designs and only those low-level routines needed to test their validity. The software implementation into the AEGIS system will be discussed in Chapter V.

B. MICROPOLIS DISK SYSTEM

Chapter II stated the general characteristics of the Micropolis disk system. This section expands on that by presenting the technical interface requirements as well as the general operation of the disk controller. For more information on the Micropolis disk unit see [Ref. 13].

1. Interface Signals

Interface to the Micropolis disk drive is made through a 34 pin edge connector located on the controller printed circuit board. The interface is structured around an 8-bit bi-directional data bus and 9 control lines. For ease of reference, the 8 data lines will hereafter be referred to as BUSØ-BUS7 with the BUSØ line corresponding to the least significant bit and the BUSØ line the most significant bit. The control line names and a complete description of each is contained in the list below. Note that in this list, reference is made to the logical condition of the signal (true = 1 and false = 0) rather than the signal's electrical polarity.

- a. SEL: Since the Micropolis controller can slave another disk unit off of it, this signal is provided to select which disk unit to use. This application only utilizes one disk unit and it is jumper configured to respond to address 0. Thus, SEL should always be 0.
- b. ENABLE: This signal is normally held true. Ir made false (2 microseconds minimum), a reset is applied to the controller logic. The controller will indicate that it is busy (through the CBUSY signal described below), important flags and registers are then initialized and approximately one second later, the controller will indicate that it is ready to accept commands from the host computer.
- c. WSTR: The write strobe is a signal from the host computer to the controller that the information on BUSØ-BUS7 is valid. The nost pulses the write strote line while driving the bus. On the trailing edge of WSTR, the controller will copy the contents of the bus into a buffer. The byte is then interpreted by the controller as either control (DATA = 0) or data (DATA = 1).
- 1. RSTR: The read strobe is a signal used by the host to indicate to the controller that it is ready to input a byte of information. When the host drives RSTR true, the controller drives the bus with the contents of either its data buffer (DATA = 1) or its status register (DATA = 0). The controller will drive the bus as long as RSTR is true.

- Thus, once the host has copied the bus, RSTR must be rade false again to regain access to the bus.
- e. DATA: This signal selects either the controller data or control ports as described above.
- f. CBUSY: The controller will set CBUSY to 0 whenever the host issues it a command. CBUSY is returned to 1 by the controller when the command is terminated.
- g. ATTN: The attention signal is set true by the controller at the end of each command. The host responds by reading the Termination Status byte from the data port.

 ATTN is set false by the controller only after the Termination Status byte has been read.
- h. DREQ: Data request is used to request the transfer of data to/from the controller. The direction of the transfer is controlled by the OUT signal. Data can only be transferred by the host in response to DREQ.
- i. OUT: This indicates the direction of data transfer. If OUT = 1, the transfer is from controller to host (a READ operation). If OUT = \emptyset , it is from host to controller (a WRITE operation).

All bus lines and control signals (except CBUSY) are active low at the interface connector. The physical interface to the 8 controller bus lines must be through an INTEL 8226 inverting bi-directional driver/receiver or its equivalent provided by the nost system. The nost must also provide 1K onm pullup resistors on each of the bus lines.

Interface to the SEL, ENABLE, DATA, WSTR, and RSTR control lines is through a 7438 inverting driver or its equivalent. The ATTN, CBUSY, DREQ, and OUT control signals are used in a DMA interface environment. If operation is in the programmed I/O mode, the DMA signals do not have to be physically connected. The logical condition of these signals can be obtained by reading the status register (see RSTR above).

2. General Operation

by writing a command byte to the command port, followed by writing six parameter bytes and a GO byte to the data port. The command byte identifies the type of command while the parameter bytes contain the control and addressing information necessary to execute it. The GO byte actually starts the command execution and can contain any value. After the controller has executed the command, a Termination Status byte is written to its data port and ATTN is set. When the nost reads this byte, the command execution is complete and the controller can accept a new command.

3. Commands and Error Recovery

Three types of commands can be executed: non-data transfer, transfers from nost to controller (write), and transfers from controller to nost (read). The non-data transfer commands are used for disk maintenance. This set of commands permit, among other things, the initialization

and/or verification of all 580 tracks associated with one of the five drive heads.

The read and write commands have three major options: operation on an entire track or a single sector, programmed I/O mode or DMA mode, and automatic retries enabled or disabled. The single sector, programmed I/O, and automatic retries enabled options were used for all read/write operations in this implementation of Micropolis. The automatic retries feature is an extremely powerful one and warrants further discussion.

automatic retries are enabled. three levels of retry are performed by the disk controller for data errors. In level one, a correction attempt is made on the data using the standard CRC-CCITT 16th order polynomial. If the correction attempt was successful, the corrected data is transmitted to the host. If not successful, a level retry is invoked. Level two will repeat the operation and correction attempt up to ten times. If still unsucessful, a level three retry begins. In level three, the read amplifier gain is increased and level one and two retries are performed. If this fails, the head positioner is offset one way then the other from the track center and level one two retries are performed again. If all retries fail, and tne command is aborted and an error condition is placed in the Termination Status byte. This feature clearly provides for a nigh degree of data integrity and error recovery.

4. Parameters

All six parameter bytes required as a part of command execution must be transmitted to the controller even though some may not be used. A description of those parameters is contained in the list below.

- a. Parm 1: Bits 4-7 contain the head address (a value between 0 and 4). Bits 2 and 3 are set to 0 and bits 1 and 2 contain the unit address. Recall that only one Micropolis disk unit is used and that its address is 0. This makes only five values valid for Parm 1 depending on the head selected: 00H, 10H, 20H, 30H, and 40H.
- b. Parm 2: This parameter contains the least significant 8 bits of the track address.
- c. Parm 3: Bits \emptyset -2 contain the most significant 3 bits of the track address and all others are set to \emptyset .
- d. Parm 4:. Contains the sector address (a value between \emptyset and 23).
- e. Parm 5: Contains the number of sectors to process. In this implementation, this value is set to 1.
- f. Parm 6: This parameter is used only in track oriented commands and since sector read/write operations were used, this byte is always set to 0.

C. PREVIOUS WORK

The Micropolis unit had been previously interfaced in an INTEL MDS single user environment by James John [Ref. 14].

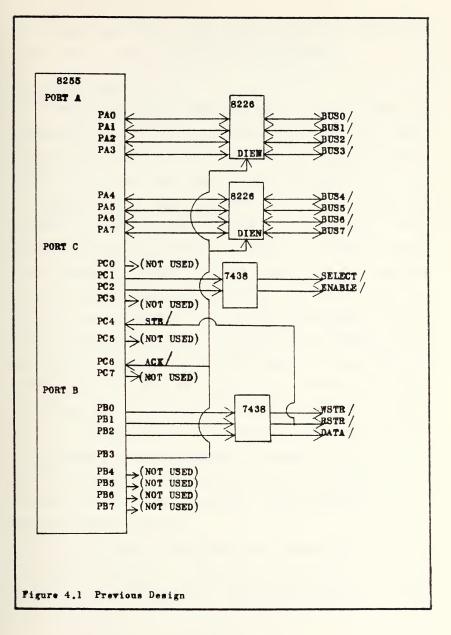

This interface was constructed using the iSBC's onboard 9255 programmable I/O device.

The 8255 can be configured in a combination of three modes: mode 0, mode 1, and mode 2. These modes and the operation of the device is discussed in detail in [Ref. 15]. In John's application, the 8255 was programmed in mode 2 and mode 0. Mode 2 provided 8 bi-directional data lines at Port A and 5 control lines for the bi-directional data port and 3 output only lines at Port C. Mode 2 provided 8 output only lines at Port B.

The required 8226 drivers with 1K onm pullup resistors are hard-wired on the 86/12A in line with the bi-directional data port of the 8255 and did not have to be added. The required 7438 drivers were inserted in sockets All and Al2 on the iSBC in line with Ports B and C. John's final interface design is depicted in Figure 4.1. (All active low signals are indicated by following the signal name with a "/", such as ACK/. This notation will be used throughout the remainder of this thesis.) Note from this figure that the STB/ and ACK/ signals needed by the 8255 to later input data and enable the tri-state output buffer are provided by wiring two of the Port B output lines into the STB/ and ACK/ inputs. These signals must be controlled locally as the disk controller provides no compatible signals.

As part of James John's work, he also reconfigured the CP/M BIOS to accommodate the Micropolis disk and two INTEL

MDS floppy disk units. This gave a complete, single user system with a total of seven accessible drives.

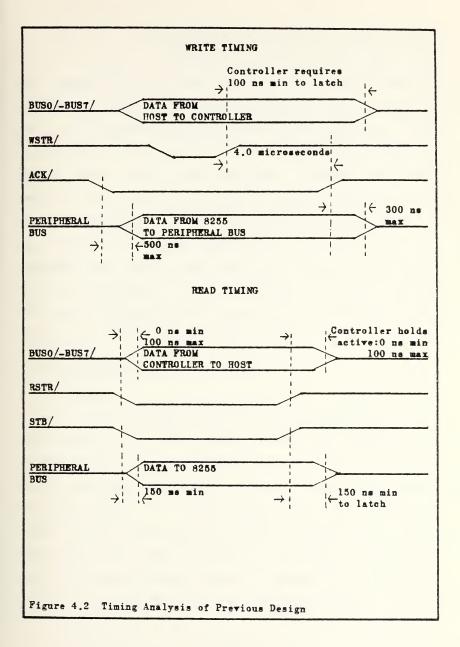

D. INITIAL EFFORTS

It was envisioned to expand on John's work to accomplish integration of the Micropolis disk drive into the AEGIS multiuser development system. Therefore, the first logical step was to set up James John's system and test it.

Various files were read from the floppy drives and written to the Micropolis drives and vice versa. This organally appeared successful. However, whenever a source code assembly language file was read and an assembly attempted on that file, the assembly continuously failed. A print-out of the source code file was obtained and various errors were found that did not exist in the original file. This led to the belief that a bad copy of the 4SM86.CMD assembler was being used and it was crashing not only the system but also the file it was operating on. A good copy of the assembler was obtained and the test repeated with continued negative results. Hardware connections were verified and re-verified. Software was also checked and rechecked. Nevertheless, numerous other experiments still produced negative results.

At this point, the design was re-examined and this uncovered the problem. A timing analysis was performed and is presented in Figure 4.2. The latch of WRITE data from

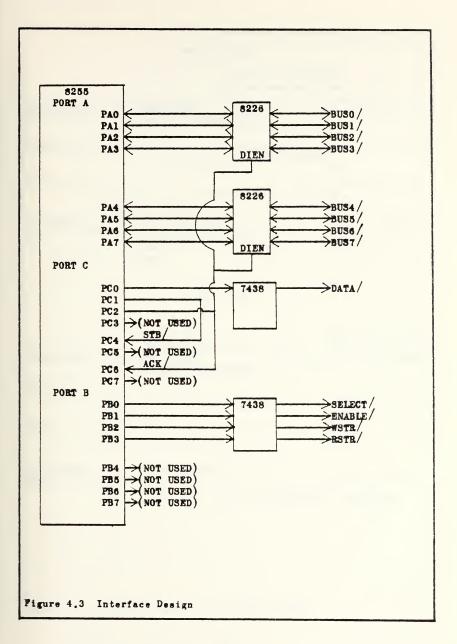

the host to the controller occurs within a valid region (window) as snown. However, the laten of RBAD data from the controller to the host does not. This occurs because the RSTR/ and STB/ signals are physically wired together. Both will go active/inactive at exactly the same time. The controller will hold the bus active only for 100 nanoseconds maximum after RSTR/ goes inactive. However, the 3255 requires 150 nanoseconds minimum to laten the data after STB/ goes inactive. Thus, the data that is latened may or may not be valid. This explains why marginal success was obtained when source files were just written to and read from the Micropolis. It also explains why random errors that were not present in the original source file were found in the file that was printed from the Micropolis.

E. NEW DEVELOPMENT

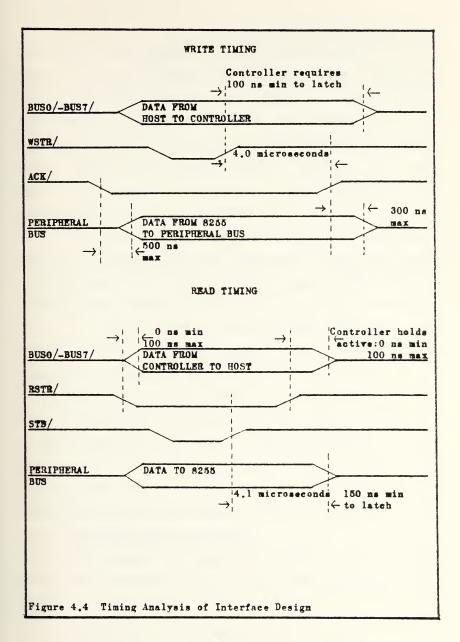

1. Design

A new interface was designed in which the ACK/, STB/, RSTR/, and WSTR/ signals were all independently controlled by setting the appropriate bit on the 8255. Because the condition of each individual signal is now under software control, it can be ensured that the data will remain valid long enough for either the controller or the 8255 to latch it. The new design is presented in Figure 4.3 and the associated timing diagram in Figure 4.4. As shown in Figure 4.4, all latching occurs in valid windows.

To write a byte of information to the controller, the byte is first written to Port A of the 8255 and the ACK/signal is set to 0, enabling the tri-state output buffer and driving the bus lines with the contents of that buffer. Next, WSTR/ is turned on (set to 1) and turned off (set to 0). The controller will copy the bus lines into an input buffer on the trailing edge of WSTR/. Finally, the tristate buffer of the 8255 is disabled by setting ACK/ to 1 and the write operation is complete.

To read a byte of information from the controller. RSTR/ is activated. This will cause the controller to drive the bus lines with its data buffer as long as RSTR/ remains active. Next, STB/ is turned on (set to 0) and turned off (set to 1). This copies the bus lines into the 8255 input buffer. Lastly, the RSTR/ signal is deactivated and the byte can be accessed by reading Port A of the 8255.

Each of the bit set/reset operations needed in the read or write functions just described, requires a MOV and an OUT instruction for a total of 20 clock periods in the 8086. With a 5 Mnz clock, this is 4.0 microseconds and clearly, more than meets the response or settling time constraints of either the 8255 or the disk controller.

2. Implementation and Testing

The design in Figure 4.3 was set up on an iS3C 86/12A. The following nardware changes were required to the board:

Remove jumpers:

E13-E14 E17-E18 E21-E25 E15-E16 E19-E20 E28-E29

Add jumpers:

E28-E15 E30-E17 E30-E25

Add 7438 drivers in sockets:

XA11 XA12

Next, a cable was constructed that would interface the J1 34 pin edge connector of the 86/12A to the J101 34 pin edge connector of the Micropolis controller. The cabling requirements are snown in Table 4.1. Those pins not shown are not required and are not connected.

The 86/12A was then placed in the iCS 80 chassis for Only the most primitive routines were written to read and write to various heads, tracks, and sectors of the Micropolis. These were executed under DDT86 to allow manual changing of the command and parameter bytes. first. single character was written to fill an entire sector and tnen read back. This was successful. Next, a text message was prepared and written to a variety of different sectors and tracks of each drive head. In each case, the message was retrieved Successfully and it was concluded that the design was functional.

F. INTERRUPT MECHANISM

1. Design

With the interface design complete, it remained to design the timer-controlled interrupt for polling common memory. The design was based on two devices available on the 86/12A: the INTEL 8253 programmable interval timer and the INTEL 8259 peripheral interrupt controller.

The 8253 has three independent 16-bit counters and each can be programmed in one of five modes. Petails of its operation can be found in [Ref. 15]. The design employed here uses only counter & and it is programmed in mode &, the "interrupt on terminal count" mode. In this mode, the output of the timer will be driven low when the mode control word is written to it. After the count value is loaded into the count port, the counter will begin counting down. Upon reaching the terminal count, the timer output will go high and remain high until a new count value is loaded.

The mode control word selected was 30ff. This gives timer 0 the following characteristics: operation in mode 0, binary 16-bit counter, and load count value as least significant byte first then most significant byte. The count value used was 300CH which corresponds to an interval of 10 milliseconds at a clock frequency of 1.23 MHZ (the clock frequency supplied to the 8253 by factory default).

Like the 8253, the INTEL 8259 has many different options available. Only those appropriate to this design

are covered in the following paragraphs. For more information see [Ref. 15].

Three initialization command words (ICW) and one operational control word (OCW) are required to properly configure the 8259. ICW1 is set to 13H. This corresponds to edge triggering, no slave interrupt controllers, and ICW3 is not required.

ICW2 is set to 40H. This is used in conjunction with the interrupt level number to arrive at the address in the interrupt vector table (see Figure 2.3) from which to obtain the code segment and offset values for the interrupt handler routine. Interrupt level 6 was chosen and this corresponds to a vector table address of:

4 # (40H + 6H) = 118H

Therefore, the address of the interrupt handler must be loaded in this location.

ICW4 is set to 0FH. This indicates 8086 mode, automatic end of interrupt, and buffered mode.

OCW1 is used to mask unused interrupts. It is set to BFH. This enables interrupt level 6 and disables all others.

2. Implementation and Testing

To implement the design simply required removing default jumper E79-E83 and connecting a jumper between E75 and E83. This connects the output of timer @ on the 8253 to the interrupt 6 input on the 8259.

A primitive routine was written that initialized both devices as described above and loaded an interrupt nandler address into the vector table. The interrupt handler was a simple routine that performed the following: saved all registers on the stack, printed a message at the console, restored all registers, and reloaded the count value into the timer. When tested, the timer-controlled interrupt functioned normally.

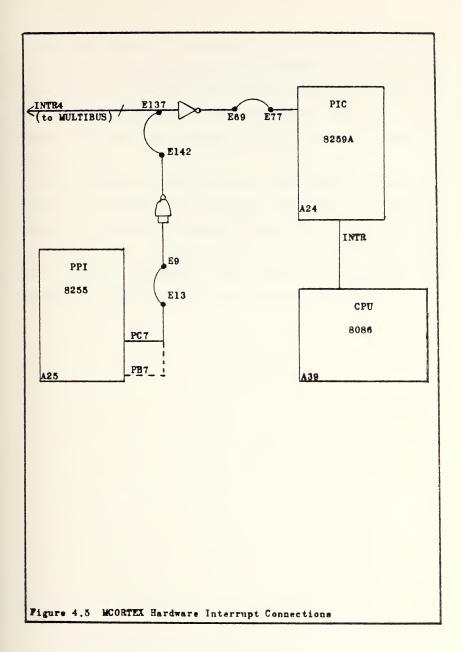

G. MCORTEX INTERRUPT

As stated in Chapter III, the MCORTEX operating system uses a type of global interrupt for message broadcasting. The hardware configuration required to achieve this is depicted in Figure 4.5. Port C or the 8255 is initialized as an output port and to "issue" the interrupt requires setting bit 7 of port C to 1.

It is envisioned that future development will allow the CP/M-86 operating system and MCORTEX to co-exist in the local RAM of each independent user on the AEGIS multiuser development system. This was taken into account in this research effort. Nevertheless, changes in the hardware and hardware initialization will be necessary before this can be achieved. Those changes are identified below.

Both MCORTEX and CP/M-86 (with the Micropolis integration), initialize the 8259 interrupt controller with exactly the same initialization command words. Interrupt

level 6 was chosen for Micropolis to be of a lower priority than the interrupt level 4 used by MCORTEX. However, recall from Section F-1 that the operational command word is set to BFH and this masks all interrupts except level 6. This value will have to be changed to AFH to activate interrupt level 4.

The MCORTEX interrupt bit will also have to be moved as snown by the dashed line in Figure 4.5. This is required because the Micropolis disk drive uses Port C as a strobed input/output port. The nardware dependent source code found in the advance, pre-empt, and initialization processes of MCORTEX will have to be updated to reflect this change.

V. SOFTWARE IMPLEMENTATION

A. MAINTENANCE SOFTWARE

Before the Micropolis disk unit could be used. It was first necessary to write a routine that would initialize and format the disk surfaces. The purpose of initialization is to write the address and data fields or each sector onto the surface. This is a controller invoked function. After initialization, the address field will contain the required head number, track number, and sector number. All data fields will contain 51H.

The purpose of formatting is to change the contents of the data fields from the 51H that resulted during controller initialization to E5H. This is necessary tecause CP/M-86 expects to find E5H in the data fields in order to create a directory space.

The routine that was developed, MICMAINT.CMD, is completely menu driven and extensive error checking is performed on all user supplied input. This routine provides not only initialization and rormatting options but also verification of initialization and verification of formatting. These additional facilities enable the user to easily uncover any disk surface defects. For an explanation of now to use MICMAINT.CMD, see APPENDIX A (User's Manual for the AEGIS System).

The Micropolis disk surfaces were successfully initialized and formatted with MICMAINT.CMD. No surface defects were found in the initialization process.

B. DEVELOPMENT OF THE DEVICE DEPENDENT ROUTINES

As stated in Chapter III, seven device dependent routines were necessary in order to interface the Micropolis disk drive into the AEGIS development system. The SELDSK, HOME, SETTRK, SETSEC, READ, and WRITE routines were developed simultaneously. This was a consequence of the Micropolis 512 byte physical sector length. The CP/M-86 operating system utilizes a 128 byte logical sector length. Therefore, a physical to logical sector mapping (blocking/deblocking technique) was required in order to communicate with CP/M. The method used had an effect on all six of these routines.

The INIT routine required special attention as it was used not only to initialize the parallel I/O port, the timer, and the interrupt controller but also to embed the the interrupt handler within the operating system. The details of both the INIT routine development and the blocking/deblocking algorithms used are given below.

1. Initialization and Interrupt Handler

The hardware initialization required for the INIT routire had been previously developed and tested (see Chapter IV). It remained to develop an interrupt handler.

Recall that the sole purpose of the interrupt handler is to effect communications between the Micropolis disk controller and the common memory. A status byte, command packet, and a 512 byte sector buffer were established in the common memory to coordinate this effort. Figure 5.1 depicts the resulting map of common memory addresses.

The status byte serves two purposes: to inform the interrupt handler that a disk read/write operation is being requested and to return the success/failure code that resulted during that operation. It is initialized to OFFH as a part of the Micropolis INIT routine. The status byte is set to 00H to request a disk operation and the interrupt handler will return 0AH if the operation was successful. If it failed, one of the nine error codes listed in the Micropolis Technical Manual pages 24-25 is returned.

The command packet consists of eight values: the command byte, six parameter bytes, and the GO byte. The parameter bytes were discussed in detail in Chapter IV. Section B-4. The GO byte can take on any value and Ø was used. The command byte used in this implementation can be either 47H for the write operation or 4EH for the read operation. These values give both the read and write operations the desired characteristics of single sector processing, programmed I/O data transfers, and automatic retries enabled.

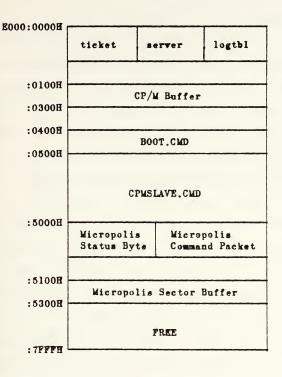

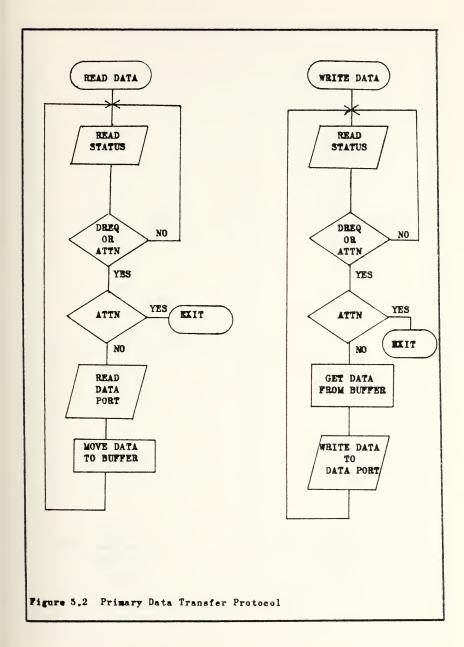

Figure 5.1 Final Common Memory Allocation Map

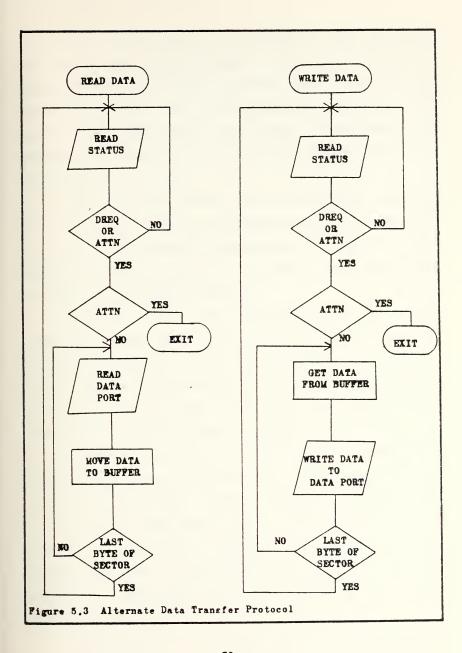

The sector buffer is used to transfer data to and from the controller. Both primary and alternate data transfer protocols are possible in the programmed I/O node and these are shown in Figures 5.2 and 5.3 respectively. alternate protocol differs from the primary protocol in The the amount of status checking required. As snown, the primary protocol requires a status check between the transfer of each data byte while the alternate does not. Use of the alternate protocol is possible only if the loop time is greater than the 1.5 microseconds/byte response time of the controller. Recall from Chapter IV that all operations require a minimum of a MOV and an OUT instruction and these two instructions need 4.0 microseconds to execute. Thus, the alternate data protocol was employed in the interrupt nandler to improve response times.

A brief description of how the resulting interrupt nandler works is in order. When the timer-controlled interrupt occurs, the interrupt nandler routine will save those registers that are needed by the routine on the stack and check the common memory status byte. If a non-zero value is found, the timer count value is re-loaded, the registers are restored from the stack, and a return is executed with no further action taken. If a zero value is found, the command byte is read to determine the direction of data transfer (to the common memory sector buffer for a read operation and from it for a write operation). Next,

the entire command packet is transmitted to the controller and when the DREQ signal is sensed, the data is transferred using the alternate protocol described above. Finally, the Termination Status byte is read from the controller and placed in the common memory status byte, the registers are restored from the stack, the timer count value is re-loaded, and a return is executed.

The interrupt nandler and initialization routines were loaded into memory and DDT86.CMD was used to manually set the interrupt handler's common memory variables. This enabled extensive testing to be carried out and the routine was found to function as designed.

At this point, the interrupt handler was being loaded into local RAM at the top of the transient program area (TPA). Because all users have access to this area, it would be quite a simple matter to write over or otherwise alter the routine and thus, disable the disk communications capability. A more practical solution had to be found. It was decided to place the interript handler immediately following the return instruction of the Micropolis INIT routine for two reasons. First, because the routine would be a part of the operating system, it would not be as easily accessible by the user. Secondly, this co-locates the routine with the initialization of the hardware used to invoke it. This makes future modifications to the routine or the technique easier.

2. Plocking/Deblocking

The physical to logical sector mapping required for the Micropolis disk system was supplied, in part, by the Digital Research DEBLOCK.LIB source file. This file is supplied as a part of the CP/M-86 operating system. It provides a complete routine for HOME, SETTRK, SETSEC, and SELDSK operations. READ and WRITE operations are also supplied but require the user developed routines READHST and WRITERST.

The READHST routine that was developed prepares the command packet described in Section 1 above and sends it to the common memory. The status byte is then changed to 0 and the routine waits for the interrupt handler to change the status byte. If the status byte indicates success, the common memory buffer is copied into a local sector buffer and the operation is complete. If an error is indicated, the error flag used by the BDOS is set and the common memory buffer is not copied.

The WRITEHST routine closely follows the READHST routine. First, a command packet is prepared and sent to the common memory. Then the local sector buffer is placed in the common memory sector buffer and the status byte is set to 2. The routine then waits for the status byte to indicate success or failure and the EDOS error flag is set accordingly. This completes the write operation.

It should be noted that in the READHST and WRITEHST routines, the status byte must be set to 0 only after the command packet and common memory sector buffer (write operations only) are set up. This is necessary because when the interrupt occurs, the interrupt handler will use the command packet and sector buffer in common memory at that time. If the status byte is set to 0 prior to preparing common memory, there may or may not be enough time to prepare it. Setting the status byte to 0 after the common memory has been prepared ensures that the intended operation will be carried out.

The DEBLOCK.LIB routines cited above were used in their entirety to provide the remaining device dependent routines. However, one minor alteration was necessary. All variable names were prefixed with "MIC". This was required because Almquist and Stevens' work used the same routines for the REMEX hard disk [Ref. 5].

C. INTEGRATION INTO THE MULTI-USER SYSTEM

To integrate the Micropolis hard disk into the multi-user system, the seven device dependent routines were placed in a single file, MICHARD.AS6. Next, the Disk Parameter Table was updated to reflect the Micropolis disk unit. Each one of the five drive heads was configured to be to a logical CP/M drive. The final logical to physical device mapping for the multiuser system is shown in Table 5.1. The

Table 5.1 Logical to Physical Device Map

calls to RECUEST and RELEASE were placed in the READ and WRITE routines, the label table file, CPMMAST.CFG, was updated, and an 'INCLUDE MICHARD.A86' statement was placed in the BIOS module. The steps of Figure 3.4 were followed and a new CPM.SYS was generated. Note that in the original system of Almquist and Stevens, this file was titled "CPMMAST.CMD". It was necessary to change the name as a result of other work accomplished during this research effort. This is discussed in the next section.

The master conditional assembly switch in the BIOS module was set to false and a CPMSLAVE.SYS file was created. The slave version is different from the master version in that the Micropolis interrupt handler and nardware initialization, as well as the intialization of common memory synchronization variables, are not included.

When the system was initially tested, it loaded properly and only certain commands, such as DIR and REN, could be executed. Commands such as PIP and STAT would not. In fact, the system would come to a halt and required rebcoting when these commands were attempted. Many experiments were conducted in an effort to find the source of this problem. It was discovered that only the built-in commands (DIR, REN, ERA, and TYPE) would execute.

The difference between a built-in command and a transient utility program is that the built-in command resides in memory as a part of the operating system while

the transient utility program resides on disk. Thus, transient utility programs, like PIP, must first reloaded in memory. This program then becomes the applications program of Figure 3.1. Any disk operations required in the process of executing the program must be performed by the BDOS module. The applications program indicates that a disk operation is required by first setting the CX register of the 8086 to the appropriate function number and then executing the software interrupt number 224. When interrupted, the BDOS module will carry out the indicated function.

This conflicts with nariware interrupts. Recall from Chapter II, Section A-4 that a software interrupt is of nigner priority than a nardware interrupt. As shown in Figure 2.4, when a software interrupt is being processed, the hardware interrupts are not sensed. A transient utility program enters the BDOS by executing a software interrupt as described above to perform any read/write operation. In this implementation, the read/write operation for the Micropolis can be completed only if the nardware interrupt occurs. Therefore, a feadlock results.

This problem was solved by executing an INT 70 instruction on the master board whenever a Micropolis read/write operation is needed. This forces the interrupt handler to execute even though the entry to the BDOS has prevented the hardware from causing its execution. The

CPM.SYS and CPMSLAVE.CMD files were re-generated as stated above and tested again. All command file executions on the master board were successful. All four AEGIS system boards were then booted and the multiuser system was tested. Simultaneous operations conducted on these four boards were also successful and it was concluded that the Micropolis disk unit had been successfully integrated into the multiuser AEGIS development system.

D. A NEW BOOT ROM AND LOADER

Early in the development stages of the Micropolis interface, it was discovered that a power failure would destroy the contents of bubble memory. Since, the operating system was booted from this device, work could not be continued until the bubble memory had been re-formatted and re-loaded with the operating system. This is an extremely time consuming task and the method is detailed in [Ref. 5, Chapter IV, Section D]. Thus, it was considered desirable to be able to boot load the operating system from the REMEX floppy disk drive. A new boot ROM and loader routine were developed for that purpose.

1. Boot Loader

As stated in Chapter III, the SK byte EPROM chips on the iSBC 86/12A contain the INTEL 957 monitor and control is passed to the monitor whenever the system RESET button is pushed. Both the bubble boot loader and the INTEL MDS

system boot loader co-exist with the monitor in this 8K EPROM space.

lt was originally thought that the REMEX boot loader could simply be added to the EPROM. However, this was not possible because the space occupied by the monitor severely limits the space available for programs. The SK EPROM onips occupy the address space between ØFE000H and ØFFFFFH. The 957 monitor occupies the space between ØFE000H and ØFFD22H and contains a set of jump vectors at the base of this address space. This leaves approximately 72V decimal bytes of space for boot loader programs. It was decided at this point to maintain the monitor and INTEL MDS system boot loader in the EPROM and to replace the bubble boot loader with the one for REMEX. This would preserve the flexibility of being able to boot load the 86/12A from two different systems instead of just one.

A boot loader simply loads the program located on the reserved system tracks of the disk into memory and passes control to it. It is the responsibility of this program, the loader, to load the actual operating system into memory and pass control to it. To develop a boot loader for the REMEX would require that a working system loader be placed on the system tracks of the diskette. Since one had not yet been written for the REMEX, the bubble system loader, LDRMB80.CMD, was used for development purposes. This would permit the boot loader under

development to load the bubble system loader from the REMEX floppy disk and this loader would then load the operating system from bubble memory. A boot loader program, RMYROM.AS6, was successfully written, debugged, and tested using this technique. The source code for the INTEL MDS boot loader was then successfully integrated into RMXROM.AS6.

2. System Loader

The system tracks of a single density, eight inch floppy disk have 6.5K bytes of storage capacity and the system loader must be limited to this size. To generate a loader BIOS module for the REMEX, a conditional assembly switch was added to the present BIOS module. The switch. "loader bios", when set to true, only includes in the assembly the device dependent code related to the REMEX floppy disk drive. A new label table file and a new Disk Parameter Table were created. These files, LDRMAST.CFG and LDRMAST.LIB respectively, reflect the REMEX floppy disk as the only disk drive in the system. The steps of Figure 3.5 were used to create the loader (It should be noted here that the LDCPM.CMD provided by Digital Research for use in the loader. expects to find the system file as CPM.SYS and this was the reason for the name change cited in Section C above). The resulting loader, RMXLDR.CMD, was approximately bk bytes and easily fit on the system tracks. The REMEX

system loader was debugged and tested using the REMEX boot loader as the test vehicle.

3. Programming the EPROM

With the boot loader and system loader routines complete, the EPROM chips could now be programmed. The 8K bytes of EPROM consist of four 2K byte INTEL 2715's. Because of the even-odd addressing used on the 86/12A, two of these occupy the even 4K byte address space while the other two occupy the odd 4K byte address space. Because the only space available for boot loaders is located entirely within the upper 4K bytes of EPROM, it was necessary only to modify the two 2716's occupying this address space.

DDT86.CMD was used to read the contents of the upper 4K bytes of the 86/12A's EPROM and this was saved as a CMD file. Again using DDT86.CMD, the existing boot loaders were removed from this file and the contents of RMYROM.CMD were inserted. This resulted in a single contiguous file containing the upper portion of the 957 monitor, a boot loader for the REMEX, a boot loader for the INTEL MDS system, and the jump vectors required by the 957 monitor.

Two routines were then written that split this file into two files: one containing the odd address bytes and the other containing the even address bytes. Two new INTEL 2716s were then programmed with the contents of these two files. The newly programmed chips were placed on the iSBC 86/12A and tested. The INTEL MDS system was successfully

boot loaded by typing the command "GFFD4:0" from the monitor and the AEGIS development system was successfully booted from the REMEX floppy disk drive by typing the command "GFFD4:4" from the monitor.

VI. RESULTS AND CONCLUSIONS

A. EVALUATION

Two tests were conducted to evaluate the performance of the AEGIS development system. The first test consisted of assembling a 6K byte file and recording the assembly time. This was done for both the Micropolis disk system and the REMEX Data Warehouse with one, two, three, and finally, four computers operating simultaneously. Timing was accomplished with a standard stopwatch. The results of this test are shown in Table 6.1

The second test consisted of file transfers using the PIP.CMD file utility. This represents a worst case situation as file transfers are I/O intensive. Four transfer directions were tested: REMEX to REMEX, Micropolis to REMEX. REMEX to Micropolis, and Micropolis to Micropolis. A single 27% byte file was used as the transfer file. Once again, the test was conducted with first one computer operating and then with two, three, and four computers operating simultaneously. The results of this test are also shown in Table 6.1.

As indicated by the assembly data, there is not a linear relationship between the number of computers in the system and the times required for assembly. In fact, with four computers, the time required for assembly of the 6K byte

	Execution times (in seconds)			
Command	One Computer Operating	Two Computers Operating	Three Computers Operating	Four Computers Operating
ASM86 REMEX	25,2	37.0	43.7	58.2
ASM86 Micropolis	30.2	49.2	62.4	76.5
PIP REMEX to REMEX	5,5	22.3	29.7	32.9
PIP Micropolis to REMEX	7.4	22.4	36.0	43.0
PIP REMEX to Micropolis	9.3	36.0	46.0	62.5
PIP Wicropolis to Wicropolis	11.5	38.9	48.6	67.3

Table 6.1 Test Data

file is roughly 2.5 times the time required with just one computer. This is accounted for by realizing that, except for the contention for shared resources (common memory and hence, disk access time), each computer can assemble the file independently of the others.

From the file transfer data, as well as the assembly data, it is immediately apparent that the REMEX Data Warehouse operates faster than the Micropolis disk system. However, this is not an order of magnitude as one might expect when comparing a DMA interfaced hard disk to one that is interfaced using programmed I/O. If the ten millisecond polled interrupt (used to communicate with the Micropolis) is taken into account, the Micropolis performance would come even closer to that of the REMEX. The reason that the programmed I/O interface performance is close to that of a DMA interface is that more time is expended in disk head movement than memory access.

B. GENERAL CONCLUSIONS

The primary goal of this thesis was met. A hardware interface was designed for the Micropolis disk drive using programmed I/O techniques and this was successfully integrated into the AEGIS multiuser system. The system was demonstrated with four independent users operating simultaneously. The addition of the Micropolis disk system to the AEGIS system provides an additional 35.6M bytes of

on-line storage capacity and should prove to be more than adequate for program and data storage. This frees the REMEX nard disk to be used entirely for the SPY-1A radar emulation rather than as a software storage media.

A boot ROM was also developed that allowed loading the operating system from the REMEX floppy disk drive. This proved to be more reliable than the bubble boot procedure used at the onset of this research. The bubble memory frequently "crashed" and required reformatting and reloading before it could be used again. The cause for this was never discovered except for noting that every time a power failure occurred, the bubble memory would crash. The board has onboard power failure protection circuitry. However, the facilities required to thoroughly test this circuitry were not available.

Future research involving the AEGIS multiuser system should include expansion of the current 8K EPROM to 16K and development of a boot loader that would allow booting from any of the devices in the system. As the current system stands, if the REMEX floppy disk drive fails, either a new boot ROM will have to be generated or the old bubble boot ROM will have to be restored. This may eventually prove to be too inflexible.

Additionally, some type of protection scheme needs to be implemented for common memory. Currently, there is no protection and a user program that has gone out of control

could quite easily destroy the data in common memory. This development would require that some type of hardware access control be designed and the BIOS module be modified to activate that hardware whenever common memory access is required.

APPENDIX A

USER'S MANUAL FOR THE AEGIS SYSTEM

A. SYSTEM CONFIGURATION

The AEGIS development system consists of: one bubble memory board, four INTEL iSEC 86/12A boards, the REMEX Data Warenouse, the Micropolis disk system, and a 32K byte common memory board. These boards must meet certain requirements in order to work properly in the system and these are described in the paragraphs that follow.

1. Master iSEC 86/12A

This board is used as the Micropolis disk unit interface and provides the bus clock and constant clock signals to the MULTIBUS. This board must be positioned in the iCS-EØ chassis in an odd-numbered slot (the slots are numbered from 1 to 16 left to right). The board requirements are:

Remove jumpers:

E13-E14	E21-E25
E15-E16	E28-E29
E17-E18	E30-E31
E19-E20	E32-E33

Add jumpers:

E28-E15	E30-E17
E30-E25	

Add 7438 drivers in sockets:

XA11 XA12

This will set up the 8255 interface for the Micropolis disk.

To provide the constant clock and bus clock:

Add jumpers:

E103-E104 E105-E106

This board must also contain the EPROM chips with the REMEX boot routines. The final requirement is that the local RAM be made inaccessible to the MULTIBUS. This is done by adding jumper E112-E114 and removing jumper E115-E128.

2. All Other iSBC 86/12A's

The remaining boards must have local RAM inaccessable to the MULTIBUS and must not provide any clock signals. To make the RAM inaccessible, add jumper E112-E114 and remove jumper E115-E128. To disable the clock signals, remove jumper E103-E104 and E105-E106.

3. REMEX Disk Drive

The Remex controller board mus be plugged into an odd-numbered slot in the iCS-80 chassis.

4. Bubble Memory

Bubble memory must be plugged into the slot containing the RUN/HALT switch (currently position 3).

5. 32K Byte RAM Board

This board can be plugged into any slot in the chassis and must be configured to start at address E0000H.

B. ACTIVATING THE SYSTEM

Before turning any power on, ensure that the RUN/HALT switch located on the front panel of the iCS-80 chassis is in the FALT position. Next power-on the equipment in the following order:

- 1. Apply power to the iCS-80 chassis by turning the OFF/ON/LOCK key to the ON position.
- 2. Turn on the REMEX disk by toggling the OFF/ON switch on the upper right of the front panel to ON.
- 3. Activate the Micropolis disk by toggling the switch on the right of its front panel to the up position.
- 4. Spin up the REMEX disk by placing the STOP/START switch located on the upper left panel to START. The green light over this switch will go out.
 - 5. Turn on all CRT's.
- 6. Toggle the RUN/HALT switch on the iCS-80 front panel to RUN.
- 7. Press the master RESET switch on the iCS-80 panel in. This generally requires more than one RESET (normally three or four). The indicator of a good RESET is that all CRT's are printing stars and that the green lights over both the START/STOP switch and the A WRITE PROTECT switch of the REMEX are on.

With the power applied, the next step is to load the CP/M-86 operating system:

- Place a system disk in the REMEX drive E (leftmost floppy drive) latel up and close the door.
- 2. From the CRT connected to the master board (the one with the Miccropolis interface cable), type "U". This will activate the INTEL 957 monitor.
- 3. Enter the command "GFFD4:4". The disk in drive B will be accessed and approximately one to two minutes later the operating system will respond with:

ENTER CONSOLE NUMBER

4. Respond with the number on the front panel of the CRT. The next request will be:

ENTER LOGIN DISK

- 5. Respond with the desired disk. This will be the only disk that you will be permitted write access to.
- 5. The master board is now operational. To activate the remaining boards, first locate any disk drive that contains the following files: LDBOOT.CMD, BOOT.CMD, CPMSLAVE.SYS, and LDCPM.CMD. Then type the commands "LDBOOT" and "LDCPM" from that drive. Next, type "U" from any uninitialized board to activate its 957 monitor. Enter the command "GEQQQ:40Q". As with the master board, you will be queried for a console number and login disk. Reply as with the master board.

C. DE-ACTIVATING THE SYSTEM

 Ensure that no floppy disks are in the REMEX and that all users have finished.

- 2. Press in the master RESET button on the iCS-80 chassis.
- 3. Place the RUN/HALT switch on the front panel of the iCS-80 chassis to the HALT position.
 - 4. Turn off the Micropolis disk unit.
- 5. Place the STOP/START switch of the REMEX disk in the STOP position. The green light over the switch will go out. When the light comes back on the disk has stopped. When this occurs, turn the REMEX power switch to OFF.
 - 6. Turn the power off to the ICS-80 chassis.
 - 7. Turn off all CRT's.

D. CREATING A SYSTEM DISK

- First, format the disk. This will have to be done
 a CP/M compatible system as the AEGIS system currently
 nas no formatting routine.
- Activate the system as described in Section B above.
 Place the formatted disk in the REMEX floppy drive B.
- 3. Locate any drive with the rollowing riles: LDCOPY.CMD, RMXLDR.CMD, CPM.SYS, and PIP.CMD.
- 4. Issue the command "LDCOPY RMXLDR.CMD" from this drive. You will be queried as to which drive to write to. Respond with "B".
- 5. Finally, issue the command "PIP B:=F:CPM.SYS" (Note nere that "F" was an arbitrary choice, as any drive with the specified files on it will work).

6. You now have a system disk. It can be tested following the activation procedures described in Section $\mathcal B$ above.

E. MAINTENANCE UTILITIES

The system currently contains maintenance utilities for the bubble memory, the REMEX Data Warencuse, and the Micropolis disk system. These are described below.

1. Butble Memory

There are two system utilities for maintenance of the bubble memory: DIAG86M.CMD and MBB80FMT.CMD. DIAG86M is a self test of the bubble and requires no user input other than the command "DIAG86" to activate it. Any faults occurring during this check are reported to the console. MBB80FMT is used to format the bubble for a CP/M environment. The user will be asked to enter the base address of the controller. Respond with "80000B". The formatter will then format the bubble memory.

2. REMEX Disk Drive

Two routines are also available for the REMEX: RMXMAINT.CMD and RMXFORMT.CMD. Before either of these routines can be successfully executed, the local RAM of the board executing them must be made available to the MULTIBUS as these routines were not written to pass information through the common memory. Therefore, jumper E112-E114 must be removed prior to execution. RMXMAINT is menu driven with

nine available functions. Select the function from the list at the console and enter that number. Since these routines are carried out by the firmware of the REMEX controller no other user input is required. RMXFORMT will format the REMEX for the CP/M environment. You will be queried as to which "head" of the disk to format. The head to CP/M logical device is given in the following list:

Head 0 Drive D Head 1 Drive E Head 2 Drive F Head 3 Drive G

Select the desired head number and enter it. No further inputs are required. You will be notified at the console when the formatting is complete. Restore jumper E112-E114 after completing all desired maintenance on the REMEX.

3. Micropolis Disk System

The Micropolis has a single menu-driven maintenance program, MICMAINT.CMD. This program must be executed only from the board containing the Micropolis interface. Prior to running it, ensure that all other system users are logged into a non-Micropolis disk. The Micropolis "nead" number to CP/M logical disk is given below:

Head	Ø	Drive	H
Head	1	Drive	Ι
Head	2	Drive	J
Head	3	Drive	X
Head	4	Drive	L

There are two types of commands in the menu: initialization and formatting. The initialization commands prepare the

disk for use and verify that there are no surface defects. The formatting commands prepare the disk for the CP/M operating system. If it is desired to run a initialization type of command, six values will be requested. These values are described below.

- a. Physical Address of Logical Sector \mathcal{Q} : This allows for a variety of logical sector mappings on the disk itself. In this system nowever, this value is currently \mathcal{Q} and this should be the response used.
- b. Sector Skew Factor: This enables the sector address to be physically skewed on the disk. Currently, the CP/M operating imposes its own skew factor and this value is also set to 0.
- c. Location of the Spare: The Micropolis has a sector sparing capability. If a bad sector is found during initialization, the spare can be written in the bad sectors place. Until a bad sector is noted, this value is 24. This will write the spare sector at the end of the track (sectors 2 23 are the only ones accessible by CP/M).
- d. Disk Head Number: Respond with the desired head number from the list given above.
- e. Starting Track: The Micropolis has 580 total tracks per head, numbered from 0 to 579. Enter the desired starting track number.
- f. Ending Track: Enter the desired ending track number. The selected command will be executed on all tracks

between the starting number and ending number. The format commands only require the last four entries from the list above with the same conditions. All format or initialize commands should be followed with the corresponding verify format/verify initialization command. These require the same entries as for the original command and ensure that the disk function selected has been properly carried out.

APPENDIX B

PROGRAM LISTING OF MICMAINT. A86

```
;Program Name : MICMAINT.A86
;Date : 9 April 1983
;Written by : Mark L. Perry
;For : Thesis (AEGIS
             : Thesis (AEGIS Modeling Group)
Advisor
             : Professor Cotton
            : This routine enables the initialization
;Purpose
              : and formatting functions to be carried out
              : for the Micropolis Disk. It is completely
              : menu-driven and explanatory in nature.

:Deescription:
                BDOS function 10 is utilized to input
;a line of edited data from the console. Backspacing
is permitted through the use of Control-H or Control-X.
Only a maximum of 3 characters can be entered. To
falter this, the value of 'buffer' must be changed. For
;a complete description of BDOS function 10, see page 29
;in "CP/M-86 Operating System System Guide" by Digital
; Research. Two error conditions are reported: (1) if
;no data has been entered and (2) if the data entered
;is non-numerical. In each case the user is prompted
for data again.

APPENDIX C

PROGRAM LISTING OF CPMBIOS. A86

```
;Prog Name : CPMBIOS.A86 (Master CPM Bios)
;Date : 5 April 1983
;Written by : Digital Research
;Modified by: Mark L. Perry
;For : Thesis (AEGIS Modeling Group)
;Advisor : Professor Cotton
;Purpose : This bios is for use with the iSB86/12A.
           : Includes login and logout routines and all
           : Read/Write operation conducted via common
           : memory. It also includes the code for
           : generating a loader for the Remex floppy
           : disk.

PROGRAM LISTING OF RXFLOP.A86

```
;Prog Name : RXFLOP.A86 (REMEX FLOPPY DISK
                        ACCESS CODE \
         : 5 April 1983
;Modified by: Mark L. Perry
        : Thesis (AEGIS Modeling Group)
Advisor
       : Professor Cotton
        : This code is an include file w/in CPMBIOS.A86.
Purpose
          It contains the code necessary to access the
          Remex floppy disk drives and generate a
          loader for them.
          This configuration is set for CP/M logical
          drives 1 (A: & B:) and 2 (C:). To alter
          change code in READ and WPITE routines.

; 7
  This Customized ROM loader for CP/M-86 has
                                             **
: 55
  the following hardware configuration:
                                             3,5
; 7
                                             22
     Processor: iSBC 86/12a
     Disk Controller:
                   Remex Data Warehouse
                                             ::
: ×
                   or the iSEC 201.202
                                             7,5
: 27
                                             77
     Memory model:
                 3030
                                             77
; **
                                             **
: 77
     Programmer: M.L. Perry
: 35
```

* This is the BOOT ROM which is resident in the 957 monitor. To execute the boot ; the monitor must be brought on-line and ; then control passed by "gffd4:0" or by effd4:0004". The first monitor command 275 * will poot to an iSFC 202 disk and the ; second command will boot to the Remex. ** First, the ROM moves a copy of its data ; to RAM at location 00000H, then it ; initializes the segment registers and the ; stack pointer. The 18259 peripheral int-* rupt controller is setup for interrupts ; * at 16H to 17H (vectors at 66646H-6665FH) ; and edge-triggered auto-EOI (end of in-;* terrupt) mode with all interrupt levels ; * masked-off. Next, the appropriate device * ; ₹ controller is initialized, and track Ø ; sector 1 is read to determine the target ; paragraph address for LOADER. Finally. ** the LOADER on track 0 sectors 2-26 and ; track 1 sectors 1-25 is read into the ;™ target address. Control then transfers ;* to the LOADER program for execution. ROM * ; # Ø contains the even memory locations, and # ;* ROM 1 contains the odd addresses. BOOT ** ROM uses RAM between 00000H and 000FFH ; * (absolute) for a scratch area. ************************
